Abstract

In place of root cause analysis, we look over the history of AI catastrophes to find common themes between these failures to develop a rudimentary guide as to what failures to expect based on the nature of a technology and means to mitigate the damage or a recommendation to unilaterally discontinue research in extreme cases. By focusing on thematic analysis instead of root cause, we can systematically identify when and where attention should be paid to safety of current generation AI systems.

1 Introduction

With current AI technologies, harm done by AIs is limited to power that we directly put in their hands. As said in [10], "For Narrow AIs, safety failures are at the same level of importance as in general cybersecurity, but for AGI it is fundamentally different." Despite AGI still being well out of reach, the nature of AI catastrophes has already changed in the past two decades. Automated systems are now not only malfunctioning in isolation, they are interacting with humans and with each other in real time. This shift has made traditional systems analysis impossible, as the other entities interacting with any given AI are neither homogeneous nor rational.

In response to this, we analyze how risks associated with complex control systems has been managed historically and contemporary AI failures to create a framework for predicting what kinds of risk are created from the operation of any AI system. We create a framework for analyzing AI systems before they fail to understand how they change the risk landscape of the systems they are embedded in.

2 Previous work

Risk of failure is a property inherent to complex systems, and complex systems are inherently hazardous [4]. At a large enough scale, any system will produce "Normal Accidents". These are unavoidable accidents caused by a combination of complexity, coupling between components, and potential harm. A normal accident is different from the more common component failure accidents in that the events and interactions leading to normal accident are not comprehensible to the operators of the system [8]. Increasing the complexity and broadening the role of AI components in a system decreases comprehensibility of the system, leading to an increase in normal accidents.

As computer control systems increased in complexity in the 70's and 80's, unexpected and sometimes catastrophic behaviour would emerge from previously stable systems [1]. While linear control systems had been used for some time (for example, a thermostat) without unexpected behaviour, adaptive control systems created novel and unexpected problems, such as "bursting". As described in [1], bursting is the phenomenon where a stable controller would function as expected for a long time before bursting into oscillation, then returning to a stable state. This is caused by the adaptive controller not having a rich enough input during the stable period to determine the unknown coefficients of its model correctly, causing the coefficients to drift. Once the system enters oscillation, the signal again becomes rich enough for the controller to correctly estimate the unknown coefficients and the system becomes stable again. The increased complexity of the more advanced technology (dynamic controller instead of a static controller) introduced a dynamic not present in previous technologies, and incomprehensible to an operator not familiar with this behavior. Worse, since this behavior only happens when the controller is controlling the real world plant, designers had no way of predicting this failure mode. Bursting can be reduced using specifically engineered

safety measures or more complex controllers (which bring even harder to understand problems), but still demonstrates that increases in complexity always bring risk.

The introduction of lethal autonomous weaponry [3] increases the danger of normal accidents not because it provides new kinds of failure or novel control system but because of the drastically increased potential harm. A machine which kills when functioning correctly is much more dangerous in an accident than one which only does harm when malfunctioning. By increasing the level of complexity and autonomy of weapons systems, normal accidents involving powerful weapons becomes a possibility.

In [9], Jonathan Uesato et al show that by training a reinforcement learner in an environment with adversarial perturbations instead of random perturbations, failure modes that would be extremely unlikely to be encountered otherwise were detected and integrated into training. This shows that AI trained to be "robust" by training in a noisy environment may have catastrophic failure modes that are not observed during training but can spontaneously occur after deployment in the real world. Adversarial training is a tool to uncover and improve these issues, but is only an engineering safety measure over the deeper issue of black box AI which are not characterized of their entire input space.

Large collections of AI failures and systems to categorize them have been created before [10] [7]. In [7], the classification schema details failures by problem source (such as design flaws, misuse, equipment malfunction, etc.), consequences (physical, mental, emotional, financial, social, or cultural), scale of consequences (individual, corporation, or community), and agency (accidental, negligent, innocuous, or malicious). It also includes preventability and software development life-cycle stage.

3 Classification schema for AI systems

We present a tags based scheme adapted from the one presented in [7]. Instead of focusing on AI failures, this schema classifies the AI systems themselves, allowing for risk analysis prior to failure or additional failures of the system. We pay particular attention to the orientation of the AI system as both a system with its own components prone to failure and a component in a larger system which depends on the AI to some degree. Any analysis attempting to divide a system into components must acknowledge the 'ambiguities, since once could argue interminably over the dividing line between part, unit, and subsystem' [6].

TODO read [6] so I'm not poaching this citation from [8]

To characterize the risk of an AI system, one of the most important factors is identifying the larger system in which the AI is a component. In an experimental setting, a genetic algorithm hacking the simulator can be an amusing bug [5], but a similar bug making its way into an autonomous vehicle or industrial control system would be potentially extremely dangerous. We look at the way an AI system is used as a component in three ways: (1) the intended use of the AI, (2) the way the AI is marketed, and (3) the way the AI is actually being implemented. Disparity between (1) and (2) can be caused by hype among those seeking profit from AI and poor communication between engineers and salespeople. Disparity between (2) and (3) can be caused by ignorance on the part of the buyer, lack of accessible instructional material, and intentional off-label use where the AI is good enough at the task despite not being designed for it. (TODO go on to argue that this separation between AI design by engineers and AI implementation is very common and a notable contributor to failure of AI systems acting as components in larger systems)

At the current technological scale, AI are not dangerous in isolation [TO CITE]. Their outputs must be connected to some means of control. This can take many forms: indrectly, with AI informing humans who then make decisions, or directly with an AI controlling the actuators of a robot or chemical plant. Any useful AI system has some degree of control over the world, and it may not be clear where the effects of the AI take place. This connection, where the output of a component (the AI) has significant effects on other components or system properties is an instance of coupling. Because there are multuple components affected by the AI and those componets are themselves coupled with other components, we frame this problem in terms of the AI and a 'target' which the AI can affect. For example, an AI meant to control the flow speed of a dam controls electrical signals from itself to the flow regulator, the actuators of the flow regulator, the flow speed of the water, and the volume of water deposited downstream in an interval of time. All four angles have unique consequnces the might be overlooked in analyzing just one of these targets.

Observability of the warning signs of an accident is important as it allows for interventions by human operators, a crucial tool in preventing accidents ("People continuously create safety" [4]). The likelyhood of timely human interventions depends on four things:

- Time delays between AI outputs and the effects of the target.

- Obervability of the system state as it's relavent to potential accidents.
- Frequency and attention paid by human operators.
- Ability of operators to correct the problem once it's been identified.

The time delay between an AI creating an output and that output affecting the target is essential to preventing accidents. Tightly coupled systems with short time delays (such as automated stock trading) are more hazardous because the system can go from apparent normalcy to catastrophy faster than operators can realize there is something wrong [TODO CITE the flash crash].

Observability and attention from human operators are needed for these time delays to be an effective component of safety. As the level of automation of a system increases, human operators become less attentive and their understanding of its behavior decreases [2]. Reliance on automated systems decreases an operator's ability to regain control over a system if an accident requires manual control. For example, if an autonamous driving system fails, the driver, now less familiar with driving, has to suddenly be in manual control. Together, observability, human attention, and human ability to correct possible failures in the system all make up a major factor in whether or not a malfunction leads to an accident.

For a given choice of target being controlled by the AI, there is maximum conceivable amount of damage that can be done by malicious use of that target. We use the figure as a cap as to the amount of harm possible. Most AI failures are not malicious [TODO cite, maybe?], so the harm done by an accident will almost always be much less than this amount.

is maximum conceivable damage a useful metric? It seems sound, however in many accidents, the harm is far greater than what seems possible from the limited scope of what the AI seems to control. Multiple connected failures are usually present at serious accidents, in a way that does more harm than either component could do on its own

The final criteria for classifying the nature and degree of risk of an AI system it its interconnectivity with other system, and their degree of complexity. Loosly coupled systems have sparse connectivity which limits the propagations of component failure into an accident, but are also less robust. Tightly coupled systems have dense connectivity and many paths between components, and often feedback loops that allow a component to affect itself in complicated ways [TODO cite umm probably the original Normal Accident Theory book]. Classifying the level of coupling of the system in proximity to the AI componenet can be difficult and nebulous, so only course categories (Loosly coupled, moderately coupled, tightly coupled) are used in this analysis as finer grained considerations are likely to become arbitrary.

The following factors are considered most significant to understanding the level and nature of the risk of any AI system:

- Disparity between design and marketing
- Disparity between design and usage
- The system which is affected by the outputs of the AI
- Time delay between AI outputs and the larger system
- System observability, level of human attention, and ability of operators to correct for malfunctioning of the AI
- The maximum damage possible by malicious use of the systems the AI controls
- Coupling of the components in proximity to the AI component

3.1 Mismarketing and Off Label Use

Mismarketing (using observed as hype) is measured on a 0-5 scale, with 1 being little or no hype and 5 being excessive hype. This can also been seen as the y axis on the famouse Hype Cycle graphs [**?**].

3.2 Observability, Human Attention, and Correctability

This measures how observable the internal state of the system is, how often and with what degree of attention a human will attend to the system, and how easy or difficult a failure of the AI component of the system is to correct once detected.

Observability is measured on a scale of 0-5, from 0 for a complete black box to 5 for AI whos relavent inner workings can be understood at a glance.

Human Attention is measured as the number of hours in a day that an operator will spend monitering or investigating the AI component when there have not been any signs of malfunction. If the system is not monitered regularly, then this is instead written as the amount of time that will pass between checkups.

3.3 Coupling

This considers other components and aspects of the environment that the AI is coupled with. Examples of coupling include taking data in from another component, transmitting data to another component, relying on the functioning of a component, having another component rely on the functioning of the AI, an aspect of the environment the AI directly or indirectly affects by its decisions. For each coupled component, score on a scale of 1-5 from loosely coupled to strongly coupled, and sum these scores to get the total degree of coupling.

3.4 Target of AI Control

All subsequent steps should be repeated for each possible target. Targets should be chosen from a wide variety of scales for the best analysis.

3.5 Time Delay From AI Output to Effect

A rough time span should be given to indicate how long it takes for the AI component in consideration to have a significant effect on the target in question. Only an order of magnitude ("minutes" vs. "hours" vs. "days") is needed.

3.6 Single Component Maximum Possible Damage

This is the amount of damage that could be done by a worse case malfunctioning of the AI component by itself. Since the actual worse case would be unimaginably unlikely or require superhuman AI in control of the AI component, we instead approximate the expected worse case by imagining a human adversary gaining control of the AI component and attempting to do as much harm as possible. This should consider both monatary damage, harm to people, and any other kinds of harm that could come about in this situation.

4 Determining Risk Using Scheme Tags

The following tables use scheme tags developed in Section 3 can be used for determining the next steps in risk assessment.

This is just here to give an outline of where I'm going, I'm not to writing this section yet.

5 Case Studies

We will analyze systems that use AI in the present, historically, and from fiction under this framework, and provide analysis of where their risk lies and what measures are recommended in those situations.

Posthumous analysis of accidents makes it very easy to point fingers at dangerous designs and failure by operators. However, safety is very difficult, and often well-intentioned attempts to increase safety can often make accidents more likely either by increasing coupling and thus complexity, or increasing centralization and thus brittleness [6]. Because of this, we will not be attempting to use hindsight to prevent accidents that have already happened. Instead we will be focusing on systems which have yet to fail but might at some point.

5.1 Roomba house cleaning robots

AI component: VSLAM mapping and naviation algorithm

Disparity between design and marketing: Low, software was designed in-house and is not built on hyped-up technologies

Disparity between design and usage: Low to Moderate. Engineers do their best to predict what will be in peoples' homes, but there may be unexpected environments which interact poorly with it (for example, very small pets that could be killed the the robot)

System Targets: (1) Movement of the robot within a person's home, (2) control over which areas of the floor have or have not been vacuumed

Time delay between outputs and effect: For (1), near instantaneous, for (2), over the course of hours or days

System observability: While operating, it is not possible to tell where the roomba will go next, where it belives it is, or where it has been unless the user is very familiar with how it works in the

context of their floor plan. Some models include software for monitering the robot's internal map of the house, but it is not likely to be checked unless something has gone wrong.

Maximum damage by malicious use: Average of a few hundred dollars per robot. Given full control of the roomba's navigation, a malicious agent may succeed in knocking over some furniture, and could also be able to destroy the roomba by driving it down stairs or into water. And the house would not be cleaned (denial of service).

Coupling of components:

- The robot is tightly coupled with the environment it is in, because it is constrantly sensing and mapping it. Small changes to the environment may drastically change its path.
- The cleanliness of the floor is coupled to the robot, failure of the robot will result in the floor being unexpectedly dirty.
- Very small items of value may be vacuumed up by the roomba with no indication of this happening without checking the vacuum bag

5.1.1 Tabular format

cell1	cell2	cell3
cell4	cell5	cell6
cell7	cell8	cell9

5.1.2 Suggested Measures

[TODO this is very ad-hoc, how do I write section 4 to direct attention towards the ones that matter?]

Advise users against using the robot in environments where it is conceivable for it to damage valuable items or itself, despite already designed safety measures in the robot to reduce the chance of this happening. This monetary risk can also be managed by having appropriate property insurance.

Warn users not to have the robot operate unattended where small pets could be killed by it if they escape their enclosure. [Sidenote: this is a very good example of an accident: your rare pet spider just happens to escape its enclosure while the robot was vacuuming and it gets sucked up. Many things are to blame: having both a valuable spider and an automatic vacuum, having an enclosure the spider can escape from, and so on, but none of these things are the cause and the accident happens despite the "safety measures" of the robot working correctly.]
